Heuristics for real-time train dispatching

MASTER THESIS

Study program: Econometrics and Operations Research

Author: Ing. Bc. Jan Švrčina
Supervisor: Ing. Miroslav Rada, Ph.D.

Prague, May 2026

Declaration on the Use of Artificial Intelligence

I confirm that artificial intelligence tools were used in the preparation of the submitted work. Specifically, they were used in the following ways:

- Identifying grammar, language, and typographic errors.

The description of said use is in the appendix.

I confirm that:

- my work is original and was prepared in accordance with ethical standards, in particular the Code of Ethics of the Prague University of Economics and Business; that all information sources used are properly cited in the work; and that any generated content has been verified by me;
- I accept full responsibility for the entire content of the thesis.

Acknowledgements

I thank my supervisor for his patience and the assistance he provided, my alma mater for the knowledge and connections it has given me, and my mother for the lifelong support of my education.

Abstrakt

Tato práce se zabývá problémem dispečerského řízení vlaků (TDP) a návrhem heuristiky schopné rozhodování pro komplexní železniční sítě v reálném čase. Naše metoda využívá přístup shora dolů pro rozhodování o trasování, motivovaný strukturní analýzou instancí, včetně bezpečnostních hledisek, a formulací pomocí cest a cyklů pro řešení konfliktů, což odstraňuje nutnost používat omezení s velkým M.

Procedury pro trasování i řešení konfliktů vycházejí z efektivního agregačního postupu a inovativní struktury grafu propojení (link graph). Agregační postup zmenšuje velikost problému a lze jej využít pro jakoukoli rozvrhovací úlohu s alokací zdrojů. Graf propojení uchovává informace o závislostech zdrojů pro aktuální výběr tras a umožňuje nám vytvářet strukturní implikační pravidla, která lze použít k identifikaci kritických částí při rozhodování o trasování a ke snížení počtu požadovaných proměnných a omezení při řešení konfliktů.

Heuristika byla použita k vyřešení většiny instancí v knihovně benchmarků DISPLIB a přinesla výrazné zlepšení rychlosti ve srovnání s vítěznými řešeními, i když za cenu občasných suboptimálních řešení. Výsledky jasně ukazují výhody a nevýhody formulace cest a cyklů a ilustrují, jak se struktura grafu propojení využívá v praxi.

Klíčová slova

problém dispečerského řízení vlaků (TDP), heuristika, agregace, graf propojení, formulace pomocí cest a cyklů

Abstract

This thesis addresses the train dispatching problem (TDP) by creating a heuristic capable of real-time decision-making for complex railway networks. Our method uses a top-down approach for routing decisions, motivated by a structural analysis of the instances, including safety concerns, and a path-and-cycle formulation for conflict resolution, which removes the need for big-M constraints.

Both routing and conflict resolution are based on an efficient aggregation procedure and an innovative link graph structure. The aggregation procedure reduces the problem size and can be utilized for any scheduling problem with resource allocation. The link graph maintains information about resource dependencies for the current route selection and allows us to create structural implication rules that can be used to identify critical parts when making routing decisions, and to reduce the number of required variables and constraints in conflict resolution.

The heuristic successfully solved the majority of the instances in the DISPLIB benchmark library and provided a significant improvement in speed compared to the winning solutions, albeit at the cost of sometimes suboptimal solutions. The results clearly demonstrate the advantages and drawbacks of the path-and-cycle formulation, and illustrate how the link graph structure is used in practice.

1. Introduction

1.1 Motivation

Railway transportation remains highly relevant today due to its efficiency, safety, and sustainability. However, the most limiting factor has always been the capacity of the required infrastructure. As a result, effective scheduling remains a critical challenge. The complexity of this problem continues to grow alongside the size and intricacy of the railway networks as well as the demand for their use.

Traditionally, scheduling was done manually by humans; only with the advancements of optimization algorithms and computational power have humans been aided by computers. This still produces a static schedule that might be unusable if a disruption occurs. This is the train dispatching problem, where the decisions are made in real-time, managing delays and conflicts as they happen. Real-time dispatching is often still only done by humans and provides a significant challenge for optimization algorithms as they need to find an acceptable solution in a matter of minutes or even seconds.

1.2 Goals

The main goal of this thesis is to develop a heuristic that is capable of train dispatching in real-time with interpretable results; a human should be able to understand the structure of the result to verify its validity.

The heuristic is evaluated on the *DISPLIB* train dispatching benchmark library (Kloster et al., 2025b) consisting of train dispatching problem (TDP) instances from real-world data. This library of instances was introduced for an optimization competition.

A significant part of this thesis is focused on the aggregation and the structural analysis of the TDP as presented in DISPLIB. This is the main innovation which allows us to use a top-down approach, reducing the problem to selecting the routes top-down and then scheduling the trains with a more concise model, as opposed to the bottom-up approach, building up the solutions by sequentially routing and resolving conflicts, which is used by the winning solutions in the DISPLIB competition.

1.3 Thesis structure

This thesis is structured in the following chapters with their contents:

1. *Introduction:* Outlines the motivation, goals, and structure of this thesis.
2. *Literature review:* Review of the pertinent literature separated into three parts, literature connected to DISPLIB, the most relevant resources inspiring the heuristic or providing key theoretical ideas, and an overview of the selected state-of-the-art in scheduling optimization.
3. *Theoretical background:* Basic theory necessary for the description of the problem. The main focus is on graph topology and the use of alternative and weighted graphs for scheduling models.
4. *Methodology:* Detailed description of the train dispatching problem, aggregation, routing, and conflict resolution.
5. *Results:* Presentation of the performance of the procedures described in methodology on the DISPLIB instances.
6. *Discussion:* Discussion of the ideas and procedures presented in the methodology chapter and discussion of the results.
7. *Conclusion:* Highlights of the main ideas presented in this thesis and overall evaluation, future work considerations.

2. Literature review

This chapter provides a review of the relevant literature separated into three parts. The first part is literature relevant to DISPLIB. The second part is a selection of the most relevant resources inspiring the heuristic or providing key theoretical ideas. The third part is an overview of selected state-of-the-art in scheduling optimization.

2.1 DISPLIB

As the goals of this thesis are evaluated on the instances in the DISPLIB library, we provide a review of the introductory paper as well as a description of the competition-winning solutions.

2.1.1 Problem and library

The train dispatching problem (TDP), with which this thesis works, is presented in *DISPLIB: A library of train dispatching problems* by Kloster et al. (2025b) alongside the collection of instances which can be used to benchmark this problem. This provides an important step for the subfield of train dispatching optimization—a unified problem format and real-life data to be used for benchmarking. The instances and competition results can be accessed from `https://displib.github.io/`.

> ... each study (on train scheduling) is typically tightly connected with a specific industrial use case. Code and data are seldom shared publicly. This fact hinders reproducibility, and has led to a proliferation of papers describing algorithms for more or less compatible problem definitions, without any real opportunity for readers to assess their relative performance. Inspired by the successful communities around MILP, SAT, TSP, VRP, etc., we introduce a common problem definition and file format, DISPLIB, which captures all the main features of train rerouting and rescheduling. (Kloster et al., 2025b)

The instances are published with best known solutions (assumed with unlimited time). For the 10-minute computation time limit, only the competition team rankings are presented, without an overview of the actual solutions.

2.1.2 Competition and solutions

Part of the presentation of DISPLIB was also the announcement of the competition for optimization using this library. The competition concluded at the Optimization and Decision

Science Conference (ODS) 2025, where the competition organizers presented the winners. Unfortunately, the materials for the solutions are not available, and only one team wrote a paper about their solution. Still, we find it essential to provide the reader with the description of other solutions. Consequently, the limited information from the book of abstracts for the ODS 2025 (Barbato et al., 2025) is summarized.

First place went to Carolin Scholl and Luka Stärk (DB Systel GmbH). Their solution is based on branch-and-bound search inspired by Monte Carlo Tree Search (D'Ariano et al., 2007), prioritizing not only lower bound improvements but also finding feasible solutions. In each step of the tree, they resolve the chronologically first conflict either by assigning precedence to one of the trains using the conflicting resource or by rerouting either train if possible. This is a bottom-up approach, only adding the necessary constraints for current conflicts.

Second place went to the Openbus team (ETH Zürich), who published a description of their solution in *Handling Conflicts in Microscopic Railway Timetabling at Scale: A Hybrid Approach* (Dubach et al., 2025b).[1] Their solution utilizes two distinct solvers which run in parallel. The first one is a logic-based Benders decomposition (LBBD) procedure (Leutwiler & Corman, 2022), where a master mixed-integer linear programming (MILP) problem performs a selection of currently available paths, a slave satisfiability modulo theories (SMT) solver creates a feasible timetable if possible (without conflicts) and a subproblem which detects conflicts and adds them to the SMT solver, which in turn adds cuts to the master problem to maintain feasibility. Figure 2.1 shows the diagram of the solver as presented in their poster. The second solver uses a simpler MILP representation which iteratively relaxes the bounds for conflicting resources and tightens the bounds for non-conflicting resources, converging to a feasible solution. Both of these solvers use a bottom-up approach after a bound-tightening procedure is applied globally. The authors argue that both of these solvers exploit different instance structures and share their bounds to improve convergence.

Third place went to Venislav Steliyanov Varbanov (independent). This solution also uses a MILP model with a decomposition to reduce the number of time variables. This idea is also used by the heuristic in this thesis, inspired by the provided description. After this aggregation of time variables, the conflicts are again resolved sequentially, similarly to the other two solutions.

We can see that while the winning solutions may differ in their model representation and optimization approach, and two of them use a certain level of aggregation, they have one thing in common—they resolve the conflicts sequentially, and thus they only need to consider the conflicts that arise in the current partial solution, and therefore the number of constraints and variables necessary to resolve the conflicts remains limited.

[1] This paper is not officially published; only a preprint is available.

2.2 Theory and heuristics

While the DISPLIB winning solutions provided the ideas for aggregating variables and linking conflict precedence decisions, they provided very little detail on the actual implementation. This section describes the relevant sources to explain the necessary theory to model the problem effectively.

The winning solution references *A Branch-and-Bound Algorithm for Scheduling Trains in a Railway Network* (D'Ariano et al., 2007). It uses an alternative graph formulation to model the train scheduling problem. With this formulation, we can model resource conflicts with alternative precedence arcs. It also describes the idea of inferred selection, meaning that choosing one precedence alternative for a resource implies precedence on other resources (the alternative is forbidden as it would produce an infeasible solution).

Job-shop Scheduling with Blocking and No-Wait Constraints (Mascis & Pacciarelli, 2002) introduces the alternative graph concept as a generalization of the disjunctive graph (Roy & Sussmann, 1964). The alternative graph is used to formulate a model for the blocking job-shop problem (BJSP), which is closely related to TDP.

Improving Real-Time Train Dispatching: Models, Algorithms and Applications (D'Ariano, 2008) provides static implication rules for the alternative graph representation that can be used for inferred selection based on the structure of TDP.

Railway Scheduling Problems and Their Decomposition (Strotmann, 2007) is a thesis that shows decomposition techniques for train scheduling. It inspired us to focus on the event graph used in this thesis and to separate the routing and conflict resolution problems.

2.3 State-of-the-art

Because the description of the solutions that are directly connected to this thesis is limited, we provide the reader with an overview of the recent state-of-the-art solutions to closely related problems in train dispatching and scheduling.

Optimizing Train Dispatching for the Union Pacific Railroad (Boccia et al., 2025) presents an automated dispatching system that is in use on a real rail network. It uses a decomposition of the problem and a global synchronizer to resolve conflicts. It is a prime example of how optimization can improve real-life solutions.

A Branch-and-Cut Algorithm for Scheduling Train Platoons in Urban Rail Networks (Chai et al., 2024) describes a mixed-integer linear programming (MILP) model for scheduling of train platoons, a problem where different vehicles are flexibly and dynamically coupled and decoupled.

The authors in *Decentralized Multi-Agent Coordination for Real-Time Railway Traffic Management* (D'Amato et al., 2025) propose the use of another emerging idea—instead of central or area-based decomposition schedulers, trains cooperate as separate agents to prevent conflicts and achieve efficient scheduling. This decentralized nature of cooperation has been successfully used on drone-related problems (Hert et al., 2023).

3. Theoretical background

This chapter covers the necessary theory used to formulate and solve our problem. The main focus is on graph topology and alternative graphs, and their relation to the train dispatching problem.

3.1 Basic definitions

While some of these definitions may feel redundant, we use them as an opportunity to establish notation. Most of the definitions are paraphrased from *Handbook of Graph Theory* by Gross et al. (2013) with notation adjusted to our needs.

Definition 3.1. A graph is an ordered pair $G = (V, E)$, where $V = \{v_1, \ldots, v_{|V|}\}$ is a set of vertices,[1] and $E = \{e_1, \ldots, e_{|E|}\}$ is a set of edges, where edge $e = \{u, v\}$, $u, v \in V$ is an *unordered* pair of vertices.

Definition 3.2. A directed graph (digraph) is an ordered pair $G = (V, E)$, where $V = \{v_1, \ldots, v_{|V|}\}$ is a set of vertices and $E = \{e_1, \ldots, e_{|E|}\}$ is a set of edges,[2] where edge $e = (u, v)$, $u, v \in V$ is an *ordered* pair of vertices.

Definition 3.3. A multigraph is an ordered tuple $G = (V, E, r)$, where $V = \{v_1, \ldots, v_{|V|}\}$ is a set of vertices, $E = \{e_1, \ldots, e_{|E|}\}$ is a set of edges and $r : E \to \{\{u, v\} \mid u, v \in V\}$ is a mapping from edges to *unordered* pairs of endpoint vertices.

Definition 3.4. A directed multigraph is an ordered tuple $G = (V, E, s, t)$, where $V = \{v_1, \ldots, v_{|V|}\}$ is a set of vertices, $E = \{e_1, \ldots, e_{|E|}\}$ is a set of edges and $s : E \to V$ is a source (start) mapping from edges to vertices and $t : E \to V$ is a target (end) mapping from edges to vertices.

An example for each type of graph is in Figure 3.1.

Remark. For the digraph in Figure 3.1, the definition allows for edges (2, 3) and (3, 2) to exist, using the same vertices, but going in the opposite direction. This is a useful property for the alternative graph definition.

Since we are mostly working with directed graphs, the following definitions are tailored for directed graphs. The following definitions of operators also abuse the notation by omitting the specification of graph G, which is included in the context of multiple graphs if necessary.

[1] Vertices are often called nodes.

[2] Commonly the edges in directed graphs are called arcs.

Figure 3.1
Graph types

Note: (A) is a graph, (B) is a directed graph, (C) is a multigraph, and (D) is a directed multigraph.

Definition 3.5. The source (start) $\mathrm{s}(e) = u$, $e = (u, v)$ is the starting vertex of edge e.

Definition 3.6. The target (end) $\mathrm{t}(e) = v$, $e = (u, v)$ is the ending vertex of edge e.

Definition 3.7. The incoming edges $\delta_{\mathrm{in}}(v) = \{e \mid t(e) = v,\ e \in E\}$ of vertex v is a set of edges e that end in v.

Definition 3.8. The outgoing edges $\delta_{\mathrm{out}}(v) = \{e \mid s(e) = v,\ e \in E\}$ of vertex v is a set of edges e that start in v.

Definition 3.9. The predecessors (in-neighborhood) $\mathrm{N}_{\mathrm{in}}(v) = \{u \mid u = \mathrm{s}(e),\ e \in \delta_{\mathrm{in}}(v)\}$ of vertex v are vertices u that are connected to v via its incoming edges.

Definition 3.10. The successors (out-neighborhood) $\mathrm{N}_{\mathrm{out}}(v) = \{w \mid w = \mathrm{t}(e),\ e \in \delta_{\mathrm{out}}(v)\}$ of vertex v are vertices w that are connected to v via its outgoing edges.

Definition 3.11. The in-degree $\mathrm{d}_{\mathrm{in}}(v) = |\,\delta_{\mathrm{in}}(v)|$ is the number of incoming edges of v.

Definition 3.12. The out-degree $\mathrm{d}_{\mathrm{out}}(v) = |\,\delta_{\mathrm{out}}(v)|$ is the number of outgoing edges of v.

Definition 3.13. A path $P = \mathrm{P}(u, v)$ from u to v is a sequence of edges $P = (e_1, \ldots, e_{|P|})$, such that $\mathrm{t}(e_{i-1}) = \mathrm{s}(e_i)$, $2 \leq i \leq |P|$, $u = \mathrm{s}(e_1)$ and $v = \mathrm{t}(e_{|P|})$.

Definition 3.14. A cycle is a path that starts and ends in the same vertex.

3.2 Graph topology

Because event graphs described later in Section 3.4.1 require certain properties or concepts such as acyclicity and topological ordering (Bang-Jensen & Gutin, 2008), we define and explain them in this section.

Definition 3.15. A directed acyclic graph (DAG) is a directed graph that contains no cycles.

Definition 3.16. A topological order O is a sequence of vertices in a directed graph $O = (v_1, \ldots, v_{|V|})$ such that $e = (v_i, v_j) \implies v_i \prec v_j$ ($i < j$, v_i appears before v_j in the sequence).

Theorem 3.1. Topological order can only be constructed for directed *acyclic* graphs.

Proof. For a path starting at u and ending at v, $u \prec v$ in the topological order, because for each $e = (x, y)$ in the path, $x \prec y$ and ordering $\prec$ is transitive. For a cycle, u and v have the same spot in the order; this is a contradiction. □

To detect a cycle and get a topological order of vertices, we use Algorithm 3.1. It is a combination of depth-first search (DFS) for cycle detection and DFS for topological sorting (Cormen et al., 2022). It runs in $\mathrm{O}(|V| + |E|)$ time complexity with $\mathrm{O}(|V|)$ required space. This algorithm allows us to do both cycle detection and topological ordering in one pass of DFS.

Remark. Algorithm 3.1 uses the binary operator + for concatenation of sequences, so for $S_1 = (a, b)$, $S_2 = (c, d)$, $S_1 + S_2 = (a, b, c, d)$.

3.3 Alternative graphs

Alternative graphs were introduced in Mascis and Pacciarelli (2002). They provide a very useful framework for modeling resource allocation problems with blocking. They are a generalization of disjunctive graphs (Roy & Sussmann, 1964).

Definition 3.17. An alternative graph is an ordered tuple $G = (V, E, A)$, where V are vertices and E are edges, the same as for a directed graph (Def. 3.2), and $A = \{a_1, \ldots, a_{|A|}\}$ is a set of disjunctive (alternative) edge pairs $a = ((u, v), (x, y))$, $u, v, x, y \in V$.

Remark. We denote the alternative $\bar{e}$ to the edge e from the disjunctive pair $a = (e, \bar{e})$.

To illustrate the concept of alternative graphs, Figure 3.2 shows an alternative graph with three disjunctive pairs.

Definition 3.18. A selection S is a set of edges obtained from the set of alternative pairs A by choosing at most one edge from each pair. The edges in this selection are selected, their alternatives (the other edges from each pair) are forbidden.

Definition 3.19. A selection S is complete if exactly one edge is chosen from each pair, otherwise it is a partial selection.

Definition 3.20. A selection S is consistent if the graph $(V, E \cup S)$ does not contain a cycle. If the graph does contain a cycle, the selection is inconsistent.

Algorithm 3.1

Topological sort with cycle detection

```
input: directed graph G(V, E)
output: () if G contains a cycle else topological order O

function DFS(v, S)
  if label(v) = InRecursion
    return True

Figure 3.2

Alternative graph

Note: Alternative edges are dotted, alternative pairs are grouped by color.

Figure 3.3

Alternative graph with selections

Note: (A) is partial inconsistent, (B) is partial consistent, (C) is complete inconsistent, and (D) is complete consistent selection. Alternative edges are dotted, selected edges are full, alternative pairs grouped by color.

To illustrate the selection terms, Figure 3.3 shows different types of selections for the alternative graph from Figure 3.2.

Definition 3.21. An alternative edge e is inferred from selection S, $S \vdash e$, if $S \cup \{\bar{e}\}$ is an inconsistent selection, meaning that the choice of e from alternative pair $(e, \bar{e})$ can be inferred from S because choosing $\bar{e}$ would be inconsistent. Similarly, we can say that one alternative edge x implies another y, $x \implies y$ if $\{x\} \vdash y$.

In the example from the graph in Figure 3.2, we can see that $(b, u) \implies (c, v)$ and $(v, a) \implies (w, b)$ etc.

Remark. It is possible to have a partial consistent selection P for which there exists no complete consistent selection C, $P \subset C$. One such case is in Figure 3.4, where $(b, u) \implies (c, v)$ and $(y, c) \implies (w, b)$. Because (c, v) and (w, b) are in the same disjunctive pair, we cannot make a consistent selection for this pair.

Figure 3.4
Partial consistent selection without possible complete consistent selection

Note: Alternative edges are dotted, selected edges are full, alternative pairs grouped by color.

3.4 Weighted graphs

To extend the descriptive ability of graphs to model problems, we assign properties to vertices or edges. One of the most common ones is to add weights to edges.

Definition 3.22. A weighted directed graph is an ordered tuple $G = (V, E, w)$, where V and E are the same as for a directed graph (Def. 3.2), and $w : E \to \mathbb{R}$ is an edge weight mapping.

Definition 3.23. The length $\mathrm{L}(\cdot)$ of a path P is the sum of the weights of each edge in the path,

$$\mathrm{L}(P) = \sum_{e \in P} w_e \tag{3.1}$$

Definition 3.24. The length of the longest path $\mathrm{L}_{\max}(\cdot)$ from u to v is

$$\mathrm{L}_{\max}(u, v) = \max_{P \in \mathcal{P}_{u,v}} \mathrm{L}(P), \tag{3.2}$$

where $\mathcal{P}_{u,v}$ is the set of all paths from u to v.

Remark. The length of the longest path can only be calculated for a graph without any positive length cycles, otherwise we could simply repeat the cycle indefinitely to prolong the path (Gross et al., 2013).

3.4.1 Event graphs

In our model, we use a weighted DAG that we call an *event graph*, where each vertex corresponds to an event, edge direction assigns precedence of events and the weight of an edge corresponds to a minimal duration between events. All events share the origin o, which determines the start of the timeline, and it is used to calculate the time of each following event.

Example

Figure 3.5 shows an event graph for 3 trains sharing resources. Edges (o, a), (o, g), and (o, u) set the earliest start of the trains, horizontal edges define the fastest passing of a section and diagonal edges ensure precedence for resources e.g., the edge (b, g) ensures that g starts after b, since section (a, b) requires the same resource as (g, h).

Figure 3.5
Event graph for three trains with shared resources

The time of the event x in the event graph can be calculated as the longest path from the origin o to x, $\mathrm{T}(x) = \mathrm{L}_{\max}(o, x)$.

Finding all the paths from o to each $x \in V$ could be very computationally demanding. Using DFS, the complexity is exponential (Homer & Selman, 2011).

The first optimization is the use of Bellman principle (Light, 2024)(Bellman, 1952),

$$\mathrm{T}(v) = \mathrm{L}_{\max}(o, v) = \max_{u \in \mathrm{N}_{\mathrm{in}}(v)} \mathrm{L}_{\max}(o, u) + w_{(u,\ v)}. \tag{3.3}$$

This principle is used by the Floyd-Warshall algorithm (Floyd, 1962) and Dijkstra's algorithm (Dijkstra, 1959) which are used for finding the shortest paths for all pairs of vertices and from a selected starting vertex respectively. Both of them could be adjusted to find the longest path within polynomial complexity, $\mathrm{O}(|V|^3)$ for Floyd-Warshall and $\mathrm{O}((|V| + |E|)log|V|)$ for Dijkstra with binary heap.

Since we already use Algorithm 3.1 to detect a cycle, we can just compute the event times in the topological order, because topological order guarantees that any predecessors are already processed.

Definition 3.25. The critical path $\mathrm{CP}(\cdot)$ for vertex v is the longest path from origin o to v.

The critical path limits the earliest start of event v; delaying any event along this path also delays the event v,

$$\mathrm{L}(\mathrm{CP}(v)) = \mathrm{T}(v). \tag{3.4}$$

Definition 3.26. Critical path edge $\mathrm{CPE}(\cdot)$ of v is the last edge of the critical path for v.

We can again use the Bellman principle to reconstruct the critical path,

$$\mathrm{CP}(v) = \mathrm{CP}(u) \cup \{(u,\, v)\},\ \mathrm{CPE}(v) = (u,\, v). \tag{3.5}$$

Algorithm 3.2 outputs the time $\mathrm{T}(\cdot)$ and critical path edge $\mathrm{CPE}(\cdot)$ for each vertex in the event graph. It runs in $\mathrm{O}(|V| + |E|)$ time complexity.

Remark. In our event graph, the first vertex in the topological order is always the origin o as it is the only vertex v with $\mathrm{d_{in}}(v) = 0$.

Example

For the event graph in Figure 3.5, the time and critical path edge output from Algorithm 3.2 is in Table 3.1. So the vertices on the critical path for a are $(o,\, a,\, b,\, c)$, for j are $(o,\, a,\, b,\, c,\, h,\, i,\, j)$ and for w are $(o,\, a,\, b,\, c,\, h,\, i,\, u,\, v,\, w)$.

Algorithm 3.2

Time and critical path predecessor calculation

```
input: weighted graph G, topological order O
output: time T and critical path edge CPE for each vertex in G
begin
  foreach v ∈ V(G)
    T(v) ← 0
    CPE(v) ← Undefined
  end

  foreach u ∈ O \ {o}
    foreach (u, v) ∈ δ_out(u)
      if T(v) < T(u) + w_{u,v}
        T(v) ← T(u) + w_{u,v}
        CPE(v) ← (u, v)
      end
    end
  end
end
```

Table 3.1

Time and critical path edge for vertices in event graph

vertex	T	CPE
a	1	(o, a)
b	4	(a, b)
c	8	(b, c)
g	4	(b, g)
h	8	(c, h)
i	12	(h, i)
j	14	(i, j)
u	12	(i, u)
v	16	(u, v)
w	18	(v, w)

4. Methodology

4.1 Problem description

Most of the train dispatching problem (TBD) description is taken from the *DISPLIB format specification* (Kloster et al., 2025a); an extensive explanation is available in the accompanying paper (Kloster et al., 2025b).

Each instance in the DISPLIB library consists of a set of trains and an objective to be minimized. All data is presented in JSON format (Pezoa et al., 2016). Each train is defined by an operation graph, which is a DAG. Each operation in the graph has the following properties:

- minimal duration
- start lower bound (optional)
- start upper bound (optional)
- list of successors
- list of required resources
  - resource name
  - release time

Data 4.1 shows an example of an operation entry in the instance JSON.

All operation graphs have one entry (start) operation, with no predecessors, and one exit (end) operation, with no successors. Each operation ends exactly when the successor operation starts (this is what we call a transition); the exit operation has no end.

Resources are anything that is required by the operation, typically physical sections of the railway network. Resources can only be used by one operation at a time and are released after the end of the operation that uses it plus the defined release time.

The minimized objective is defined by objective components, each with the following properties:

- train
- operation
- threshold
- coefficient (linear objective)
- increment (stepwise objective)

Remark. While the format allows both coefficient and increment to be non-zero, in practice none of the instances combine both in one objective component.

Data 4.2 shows an example of an objective component entry in the instance JSON. The total objective delay Δ is defined as the sum of components for active operations only,

$$\Delta = \sum_{o \in O_{a,\Delta}} c_o \max\{0, t_o - \bar{t}_o\} + d_o H(t_o - \bar{t}_o), \tag{4.1}$$

where $O_{a,\Delta}$ is a set of active operations that have an objective component, t_o is the start of the operation, $\bar{t}_o$ is the threshold for the operation, c_o is the linear objective coefficient, d_o is the stepwise objective increment, and $H(\cdot)$ is the Heaviside step function (Abramowitz & Stegun, 1972).

A solution to the problem is a sequence of events, each event entry corresponds to the start of an operation and contains:

- train
- operation
- time

The solution is also presented in JSON format, Data 4.3 shows a truncated solution example. To reiterate, the end event of an operation is the start event of its successor. A feasible solution for an instance meets the following requirements:

- The sequence of events is given in chronological order, i.e., the time of each event is greater than or equal to the time of all preceding events.
- The subsequence of operations applying to each train forms a path through that train's operations graph, starting at the entry operation and ending at the exit operation.
- The time value of each start event satisfies the lower and upper bounds on the start time of the operation.
- The duration from each start event to the corresponding end event must be greater than or equal to the minimum duration of the corresponding operation.
- For any pair of operations o_1 and o_2, where:
  - the start event of o_1 precedes the start event of o_2 in the global sequence, and o_1 and o_2 belong to different trains, and
  - o_1 and o_2 use a common resource r,

  the following must hold:
  - the end event for o_1 precedes the start event for o_2 in the global sequence, and
  - the duration from the end event of o_1 to the start event of o_2 is greater than or equal to the release time of resource r in o_1.

(Kloster et al., 2025a, Feasible solution requirements in DISPLIB format specification)

While the events in the solution have a time, their order in the events list is still significant, as they define in which order the resources are unlocked and locked. This is to prevent a resource swap situation described in Section 4.1.2.

4.1.1 Example problem

To illustrate the format we have prepared an example problem, the railway network diagram is in Figure 4.1. The network consists of 3 trains, 18 operations, and 8 railway sections, corresponding to resources.

Figure 4.1
Example railway network

The corresponding operation graph for train 0 (the first train) is in Figure 4.2, JSON entry for operation 4 is in Data 4.1, and JSON entry for objective component for the last operation is in Data 4.2.

Figure 4.2
Operation graph for a train

4.1.2 Resource swap

Consider the situation as in Figure 4.3, where two trains a and B are passing a section of two resources X and Y in opposite directions. If we were to set events A2 and B2 to the same time, we would not have a resource collision on either resource (overlap of intervals for operations

Data 4.1

JSON operation entry

```

        ...
    ],
    "objective_value": 25
}
```

A1 and B2 on resource X or A2 and B1 on resources Y) but, in reality, the trains would collide.

Figure 4.3
Resource swap on the railway

In this situation, resource Y is being acquired by A while holding X, and X is being acquired by B while holding Y. We can detect the resource swaps using an event graph by cycle detection, as in Figure 4.4 where A2 and B2 form a cycle.

Figure 4.4
Resource swap event graph

Remark. Using cycles in event graph to detect resource swaps only works if all resource precedence edges are present, otherwise we still might have a resource swap situation because the current event times do not create a collision and one or both of the edges that would create the cycle in the event graph are missing.

4.2 Problem aggregation

To effectively model the problem we aggregate the operations and resources from the initial problem into several interconnected structures.

4.2.1 Junctions

The first aggregation is what we call junctions, corresponding to a single event of one operation starting and one ending (except for starting and ending operations). Because we always want each operation to have a single determined event for start and end, the junction graph

is a directed multigraph, where each edge corresponds to an operation (as opposed to an operation graph where each operation is a vertex). Figure 4.5 shows an example of an operation graph with corresponding junction graph. We use the term junctions as conceptually, the operations converge and diverge in these points as in real railway junctions.

Figure 4.5
Operation graph and junction graph

Note: Operation graph is left, junction graph is right.

Aside from a more natural representation of using vertices as single events and edges as intervals, which translates to the event graph, we also reduce the number of required vertices and edges, for the example in Figure 4.5, the reduction is from 9 vertices and 11 edges to 7 vertices and 9 edges; this includes the often redundant start and end events.

Disjoint set

To aggregate the variables into junctions, we use a *disjoint set* (Galler & Fischer, 1964). It is often called the *union-find* data structure. Its use is to partition elements into non-overlapping (disjoint) sets. It has two basic operations:

- *Find:* Returns to which set the item belongs, usually by returning the representative element. Find is a unary operation.
- *Union:* If the two elements belong to different sets, it merges them together. Union is a binary operation.

In short, each element has a parent entry, which is initialized at the start to itself and the representative element of a set always has the parent as itself. To get the representative we traverse the tree upwards via the parent entries until we find the representative. When we use the union operation on two elements from different sets, the representative of one becomes a representative of the other (if they belong to the same set nothing happens).

To optimize the data structure we use path compression (flattening of the parent tree by assigning the parent of the element to its parent when traversing the tree) and union by size (always attaching the smaller tree to the larger set)(Tarjan, 1975). Both operations with optimizations are in Algorithms 4.4 and 4.5.

Algorithm 4.4

Disjoint set - find

```
input: element v
output: representative s

begin
  while u ≠ parent(u)
    parent(u) ← parent(parent(u))
    u ← parent(u)
  end
  s ← u
  return s
end
```

Algorithm 4.5

Disjoint set - union

```
input: elements u and v
output: none

begin
  u ← find(u)
  v ← find(v)
  if u ≠ v
    if size(u) < size(v)
      parent(u) ← v
      size(v) ← size(v) + size(u)
    else
      parent(v) ← u
      size(u) ← size(u) + size(v)
    end
  end
end
```

Procedure

The procedure to create the junctions is done for each train separately.

1. Create a disjoint set for each operation of the train.
2. For each operation o we use the *union* operation on each consecutive pair of successors $\{x, y\}$, $x, y \in \mathrm{succ}(o)$.
3. Each disjoint set of operations is a set of outgoing operations $\delta_{\mathrm{out}}(j)$ for junction j.
4. Add the end (sink) junction j_{end} that represents the end of the exit operation o_{exit} for the train; it has no outgoing operations.
5. Assign the source junction $\mathrm{s}_{\mathrm{junct}}(o) \leftarrow j$ for each operation $o \in \delta_{\mathrm{out}}(j)$.
6. Assign the target junction $\mathrm{t}_{\mathrm{junct}}(o) \leftarrow \mathrm{s}_{\mathrm{junct}}(x)$ to any of its successors $x \in \mathrm{succ}(o)$ (they all must have the same starting junction because of step 2.).
7. Assign the target junction $\mathrm{t}_{\mathrm{junct}}(o_{\mathrm{exit}}) \leftarrow j_{\mathrm{end}}$ to the end (sink) junction of the train.
8. Assign each junction the set of incoming operation $\delta_{\mathrm{in}}(j) \leftarrow \{o \mid \mathrm{t}_{\mathrm{junct}}(o) = j\}$.

Invalid transitions

We could have a possible situation where the set of outgoing operations $\delta_{\mathrm{out}}(j)$ for a junction j is not equal to the set of successors $\mathrm{succ}(o_{\mathrm{in}})$ for an incoming operation o_{in}, $\delta_{\mathrm{out}}(j) \neq \mathrm{succ}(o_{\mathrm{in}})$, or vice versa the set of incoming operations $\delta_{\mathrm{in}}(j)$ for a junction j is not equal to the set of predecessors $\mathrm{pred}(o_{\mathrm{out}})$ for an outgoing operation o_{out}, $\delta_{\mathrm{in}}(j) \neq \mathrm{pred}(o_{\mathrm{out}})$. This generates an invalid transition $(o_{\mathrm{in}}, o_{\mathrm{out}})$, such that $o_{\mathrm{in}} \in \delta_{\mathrm{in}}(j)$ and $o_{\mathrm{out}} \in \delta_{\mathrm{out}}(j)$, but $o_{\mathrm{out}} \notin \mathrm{succ}(o_{\mathrm{in}})$ or $o_{\mathrm{in}} \notin \mathrm{pred}(o_{\mathrm{out}})$. This case is rare and only affects a few instances, but it should be checked when making routing decisions.

An example of an invalid transition is in Figure 4.6, where the transition (2, 3) in the third junction is invalid.

Figure 4.6
Operation graph and junction graph for invalid transition

Note: Operation graph is left, junction graph is right. Junction with invalid transition (2, 3) is gray.

4.2.2 Levels

The second step is aggregation to levels. We group parallel junctions into levels,[1] since junctions can be parallel. This is useful to reduce the number of required vertices for each train in the event graph. An example of a junction graph and its corresponding level graph is in Figure 4.7.

Figure 4.7
Junction graph and its corresponding level graph

Note: Junction graph is at the top, level graph is at the bottom. Optional levels are gray.

Each level L consists of a set of junctions $j \in L$ that are parallel and thus mutually exclusive. The incoming and outgoing set of operations for each level is the union of the incoming and outgoing operations of its junctions, respectively,

$$\delta_{\text{in}}(L) = \bigcup_{j \in L} \delta_{\text{in}}(j), \tag{4.2}$$

$$\delta_{\text{out}}(L) = \bigcup_{j \in L} \delta_{\text{out}}(j). \tag{4.3}$$

Each operation also has a starting (source) level and ending (target) level based on its starting (source) and ending (target) junction,

$$\mathrm{s}_{\text{level}}(o) = L \iff \mathrm{s}_{\text{junct}}(o) \in L, \tag{4.4}$$

$$\mathrm{t}_{\text{level}}(o) = L \iff \mathrm{t}_{\text{junct}}(o) \in L. \tag{4.5}$$

The start (source) level contains only the start (source) junction, and the end (sink) level contains only the end (sink) junction.

[1] In Dubach et al. (2025b) they call levels *event clusters*, the level term was taken from Venislav Varbanov.

Algorithm 4.6

Topological generation algorithm

```
input: junction graph G(J, O), junctions J (vertices), operations O (edges)
output: levels (L_0, ..., L_n) (sets of junctions)

begin
  foreach j ∈ J
    indeg(j) ← d_in(j)
  end

  k ← 0
  Z ← {j_start}

  while Z ≠ ∅
    L_k ← Z
    Z ← {}
    foreach i ∈ L_k
      foreach (i, j) in δ_out(i)
        indeg(j) ← indeg(j) − 1
        if indeg(j) = 0
          Z ← Z ∪ {j}
        end
      end
    end
    k ← k + 1
  end

  return (L_0, ..., L_n)
end
```

Required and optional levels

Not all levels need to be passed when traversing the graph. We call such levels optional, and the levels that have to be passed when traversing the graph we call required. Dubach et al. (2025b) use the concept of required levels to generate bound constraints. We use required levels to identify border levels, which are used to create routing sections in 4.2.4. In the example from Figure 4.7 the grayed-out levels are optional, because they can be bypassed by an operation.

Topological generations

To aggregate the junctions into levels, we use the concept of *topological generations* (Hagberg et al., 2008). To create these generations we use an adjusted version of Kahn's algorithm for topological sorting (Kahn, 1962), where we group all junctions (vertices) currently without incoming operations (edges) into a level as shown in Algorithm 4.6.

Procedure

We apply Algorithm 4.6 to each train separately. We also assign each level its incoming and outgoing operations and assign each operation its source and target level.

To get required levels, we first label all levels as required and then iterate over all operations and check which levels it bypasses (if any), and mark those as optional.

4.2.3 Routes

Now that we have aggregated distinct operation start and end events into junctions and levels, we aggregate the routing decision into routes. Each route R consists of a set of operations such that if operations x and y are in the same route and y is a successor of x then x is the *only* predecessor of y and y is the *only* successor of x, and to reduce the number of routes we enforce the implication in the opposite direction as well,

$$((x \in R) \wedge (y \in R) \wedge (y \in \mathrm{succ}(x))) \iff ((\mathrm{succ}(x) = \{y\}) \wedge (\mathrm{pred}(y) = \{x\})). \tag{4.6}$$

This follows the train flow network definition in (Fuchs et al., 2025). An example of how operations are grouped into routes is in Figure 4.8.

Remark. If operation y is a successor of x then x is a predecessor of y,

$$y \in \mathrm{succ}(x) \iff x \in \mathrm{pred}(y). \tag{4.7}$$

The activation z_R of route R is equal to the activation of its operations z_o,

$$z_R = z_o, \forall o \in R. \tag{4.8}$$

Figure 4.8
Junction graph and route graph

Note: Junction graph is at the top and route graph is at the bottom. Non-routing junctions are gray.

This assignment of routes also generates a set of routing junctions (a junction is a routing junction if any route ends and/or begins there), each having a routing (flow) constraint,

$$\sum_{R \in \rho_{\text{in}}(j)} z_R - \sum_{R \in \rho_{\text{out}}(j)} z_R = \begin{cases} -1 & \text{if } j \text{ is a start (source) junction} \\ 1 & \text{if } j \text{ is an end (sink) junction} \\ 0 & \text{otherwise} \end{cases}, \tag{4.9}$$

where z_R is the activation of R, $\rho_{\text{in}}(j)$ is a set of incoming routes and $\rho_{\text{out}}(j)$ is a set of outgoing routes for junction j.

For non-routing junctions, the constraint is redundant as it has only one incoming and one outgoing route which are the same.

Procedure

For each train we iterate over operations in topological order and assign them the same route if it is the only successor of its only predecessor, otherwise we create a new route. Procedure follows Algorithm 4.7.

Algorithm 4.7

Route assignment

```
input: operations O = (o_0, ... o_n) in topological order
output: route assignment R : O → Z_0^+

begin
  k ← 0

  foreach o ∈ O
    if {p} = pred(o) ∧ {o} = succ(p)
      R(o) ← R(p)
    else
      R(o) ← k
      k ← k + 1
    end
  end

  return R
end
```

4.2.4 Routing sections

To separate what routing decisions are connected to each other and which are independent, we now group routes into sections. Each section starts and ends at a border level. Border levels are identified using conditions in the following subsection. Example of a junction graph being split into sections is in Figure 4.9.

Figure 4.9
Junction graph with identified sections and levels

Note: L0, L2, L4, and L7 are border levels. Non-routing junctions are gray.

Border levels

A border level is a level that meets the following conditions:

(a) The level is required.
(b) All junctions $j \in L$ for level L are routing junctions.
(c) For each incoming operation $o_{\text{in}} \in \delta_{\text{in}}(L)$ of level L, the successor set of o_{in} is equal to the set of outgoing operations of L, $\text{succ}(o_{\text{in}}) = \delta_{\text{out}}(L)$.
(d) For each outgoing operation $o_{\text{out}} \in \delta_{\text{out}}(L)$ of level L, the predecessor set of o_{out} is equal to the set of incoming operations of L, $\text{pred}(o_{\text{out}}) = \delta_{\text{in}}(L)$.

Condition (a) ensures that each section starts and ends at a required level. Condition (b) ensures that we do not split a route by the border level. Conditions (c) and (d) ensure that the choice of the outgoing route for the level is independent of the incoming route.

Remark. A sufficient set of conditions to replace conditions (c) and (d) is:

- The level has one junction.
- That single junction has no invalid transitions.

This is due to the nature of how we create the junctions in the first place. If a level L has a single junction j, then $\delta_{\text{in}}(L) = \delta_{\text{in}}(j)$ and $\delta_{\text{out}}(L) = \delta_{\text{out}}(j)$, and there are no invalid transitions in this junction, then the following equations hold,

$$\delta_{\text{in}}(L) = \delta_{\text{in}}(j) = \text{pred}(o),\ \forall o \in \delta_{\text{out}}(L), \tag{4.10}$$

$$\delta_{\text{out}}(L) = \delta_{\text{out}}(j) = \text{succ}(o),\ \forall o \in \delta_{\text{in}}(L). \tag{4.11}$$

Start and end levels

The start level (source) and end level (sink) are always border levels,

(a) The start level (source) and end level (sink) are always required.
(b) The start level (source) and end level (sink) always have one junction, the start (source) and end (sink) junction, respectively.
(c) There are no incoming operations for the start (source). The end (sink) level has one incoming operation, the exit, which has no successor.
(d) There are no outgoing operations for the end (sink). The start (source) level has one outgoing operation, the entry, which has no predecessor.

Procedure

For each train we do the following:

1. Identify the border levels with the aforementioned conditions.
2. Assign consecutive sections ($S_0, \ldots, S_n$) based on border levels.
3. Add all routes R within border levels (using its operations' levels) to the specified section $S \leftarrow S \cup \{R\}$.

Example

In the example from Figure 4.9, we can see that L1 satisfies conditions (c) and (d) for a border level, but it is not required, and its junction is non-routing, so it does not satisfy condition (a) and (b).

We can also see that L3 satisfies conditions (a), (c), and (d), but again, its junction is non-routing, so (b) is not satisfied.

Levels L5 and L6 satisfy (a) and (b), but (c) and (d) are not satisfied. This is because the top and bottom outgoing operations of L4 have different disjoint successor sets, thus different ending junctions, and, respectively, the top and bottom incoming operations of L7 have disjunct predecessor sets, and thus different junctions as well.

4.2.5 Resource chunks

So far we have only done aggregation based on the operations and their successors. Now we do aggregation based on the resources. While this is inspired by Dubach et al. (2025b), the implementation may differ as the authors did not provide us with sufficient details, only the conditions that are used to create the chunks.

The goal is to merge the resource uses of the same resource for directly connected operations (by predecessor and successor sets) as well as merge parallel uses of the resource. What we

do not want to group is resource reentries, where one train acquires a resource, releases it, and then acquires it again. Figure 4.10 shows an example of how operations using the same resource are merged.

Figure 4.10
Resource chunks

Note: Operations using the selected resource are red. (A) are chunks after direct merges, (B) is an invalid chunk with reentry, (C) and (D) are valid chunks after parallel merges.

The (B) case in Figure 4.10 shows an invalid chunk, where the operations on the top have a reentry of the same resource, thus they cannot be in the same chunk.

While direct merges might feel sufficient, in the following Section 4.3, we are creating a data structure that grows with the amount of chunks, so reducing the number of possible chunks is helpful to reduce the requirements of said structure.

Each chunk $c = (r_c, O_c)$ is defined by the source r_c and its set of operations O_c. Chunk c is active $z_c = 1$ if and only if any operation $o \in O_c$ is active,

$$z_c = 1 \iff \exists o \in O_c,\ z_o = 1. \tag{4.12}$$

Each operation o also has its set of chunks C_o, one chunk for each resource it requires.

The start of the chunk is the start of its first active operation (this holds for start junction, level, and time). The end of the chunk is the end of its last active operation (this again holds for start junction and level; end time of the chunk is the end time of the last active operation plus the release time for the resource).

Procedure

We apply the following procedure for each train separately and for each resource that is used by the train:

1. Get a set of all operations for a train that are using the selected resource r.
2. Create a *disjoint set* data structure, same as in Section 4.2.1, for each operation in this set.
3. For each operation, union the sets of each predecessor and each successor with the operation if they share the same resource. These are the direct merges.
4. Iterate over the pairs of disjunct sets $\{O_a, O_b\}$ and check if any operation $y \in O_b$ is reachable from any operation $x \in O_a$, and vice versa, check if any operation $x \in O_a$ is reachable from any operation $y \in O_b$. If they are not reachable, union O_a and O_b. These are the parallel merges. Note: This is an iterative procedure, the following checks to other chunks are done for the whole merged set of operations, $O_c = O_a \cup O_b$.
5. Assign each chunk $c \leftarrow (r, O_c)$ its set of operations O_c and add c to the set of chunks $C_o \leftarrow C_o \cup \{c\}$ for each operation $o \in O_c$.

Remark. To check the reachability we use a simple breadth-first search (BFS) (Moore, 1959), from the starting set of operations, that has a cutoff based on the maximum level of the target operations to reduce the search space.

4.3 Link graph

This section describes a data structure that is used to generate implication rules for resource precedence of chunks. This is useful to reduce the number of required variables and constraints in the following model for conflict resolution. We also use it to explore how routing decisions change the implication rules and how these decisions may cause unwanted effects for scheduling.

While the implication rules for resource precedence are discussed in Mascis and Pacciarelli (2002), and D'Ariano (2008) shows the structural implication rules for train scheduling, the only relation to routing is in Dubach et al. (2025b) where they only use a specific set of conditions.

We try to broaden the set of conditions that can be used to generate the structural implication rules by searching matching pairs of chunk conflicts using this data structure. Because we are maintaining a set of links between chunks, we are calling it *link graph*.

4.3.1 Resource chunk links

Resource acquisition is done in a blocking manner. This means, that to transition from operation x to y, we need to acquire all the resources r_b, $b \in C_y$ for the chunks C_y of operation

y before we can release the resources r_a, $a \in C_x$ for the chunks C_x of operation x. Because of this relationship, we say that the chunks C_x are *linked* to chunks C_y, so each chunk $a \in C_x$ has a forward link $f = (a, b)$ to each chunk $b \in C_y$, and each chunk $b \in C_y$ has a backward link $g = (b, a)$ to each chunk $a \in C_x$.

Each operation o can have multiple chunks, so we create both forward $f = (a, b)$ and backward $g = (b, a)$ for each pair of chunks (a, b), $\forall a, b \in C_o$, $a \neq b$, creating what we call a direct link as opposed to the aforementioned transition link. The set of all forward links are what we call the *forward link graph* $\mathcal{F} = (C, F)$, the set of all backward links are what we call *backward link graph* $\mathcal{G} = (C, G)$, where vertices are the chunks and edges are the links.

Remark. We keep track of forward links F_c and backward links G_c for each chunk c separately, so we can have $(c, a) \in F_c$ and also $(c, a) \in G_c$ at the same time, which is the case for direct links on chunks on the same operation o, where $c, a \in C_o$.

It is important to note that the link is active if any of the transitions (x, y) that create it are active (both x and y are active), or it is a direct link via the operation o that is active. Figure 4.11 shows both a transition and a direct link example.

Figure 4.11
Resource chunk link

Note: Operations have their chunk sets. Chunk a is blue, chunk b is red. Transition link is at the top, direct link is at the bottom.

4.3.2 Conflicts and precedence

A conflict $k = \{c_m, c_n\}$ is a pair of chunks c_n and c_m on the same resource $r = r_{c_m} = r_{c_n}$ and for different trains $m = \text{train}(c_m) < \text{train}(c_n) = n$.[2] We resolve each conflict by assigning precedence $p_k = 1 - \bar{p}_k$, meaning that if $p_k = 1$, the resource r is released by c_m before it is acquired by c_n, if $\bar{p}_k = 1$, the resource r is released by c_n before it is acquired by c_m.

We can model this situation using alternative graph where each vertex is an event (junction or level), each edge is an operation and the alternative pair is the precedence decision. Figure 4.12 shows the alternative graph for a conflict. By assigning precedence $p_k = 1$, we select edge (j_m, i_n) from the alternative pair $((j_m, i_n), (j_n, i_m))$ and vice versa.

[2] We select $n < m$ to clearly define which train is first based on the precedence.

Figure 4.12
Alternative graph for conflict

Note: Alternative edges are dotted. Chunks are in curly braces.

Remark. Without the information about the resources before and after the conflict, we cannot determine if the trains pass the resource in the same or opposite direction. This can be seen from Figure 4.12 where both alternative graphs are equivalent.

4.3.3 Conflict links

Because the trains pass the chunks continuously and in a blocking manner, there are structural implication rules for precedence for conflicts on these neighboring chunks. This is discussed in D'Ariano (2008), and we paraphrase these rules here.

There are two basic cases, trains going in the same (parallel) direction and trains going in the opposite direction. The first case has already been shown in Section 3.3, but we reiterate it here to show how the inferred selection in alternative graphs relates to the chunk precedence. The parallel case is shown in Figure 4.13.

Figure 4.13
Conflict links - parallel case

Note: Alternative edges are dotted. Chunks are in curly braces. Conflicts are distinguished by color.

As we can see, the precedence $p_a \implies p_b$,[3] because $(i_m, h_n) \implies (j_m, i_n)$ in the alternative graph. Similarly, $p_b \implies p_a$ for $(j_m, i_n) \implies (i_m, h_n)$, so $(p_a \iff p_b) \equiv (p_a = p_b)$.

[3]There is a slight abuse of notation where we use $p_{k_a} = p_a$.

Because the precedence decisions p_a and p_b imply each other, we say that conflicts k_a and k_b are linked.

Similarly, we can also see from Figure 4.13 that $p_b = p_c$, so k_b is linked to k_c. Because k_a and k_b are linked, and k_b and k_c are linked, we say that conflicts k_a, k_b and k_c form a conflict chain $\Gamma = \{k_a, k_b, k_c\}$, whose precedence decisions are equal, meaning that for all of these conflicts and their chunks, either train m or n is first, they cannot change their order.

The second case is the opposite direction case, where trains pass the resources in the opposite directions. This case is shown in Figure 4.14. Using the same logic as for the parallel case, we can see that k_a and k_b are linked, $p_a = p_b$, because $(i_m, j_n) \implies (j_m, i_n)$ and $(j_m, i_n) \implies (i_m, j_n)$. Again we can also see that $p_b = p_c$, so k_a, k_b, and k_c form a chain for this case as well.

Figure 4.14
Conflict links - opposite case

Note: Alternative edges are dotted. Chunks are in curly braces. Conflicts are distinguished by color.

4.3.4 Finding conflict links and chains

While the shown cases are trivial, in practice, we do know which direction the trains are passing,[4] so we need to use the forward and backward link graphs $\mathcal{F}$ and $\mathcal{G}$ to figure out the direction.

Remark. The main motivation for the link graph is that finding the linked pairs of conflicts exhaustively is computationally expensive, and while the inferred selection conditions in the literature are theoretically sufficient, they are impractical to check for problems of the size found in DISPLIB.

To find if there exists a link between two conflicts $k_a = (a_m, a_n)$ and $k_b = (b_m, b_n)$ we can check the link graphs for a matching chunk links. So conflicts k_a and k_b have a parallel link if either of the following conditions hold:

[4]Trains might also be parallel in one section and opposite in another section of the track.

(1) Chunk a_m has a forward link $(a_m, b_m) \in F_{a_m}$ and a_n has a forward link $(a_n, b_n) \in F_{a_n}$.
(2) Chunk a_m has a backward link $(a_n, b_m) \in G_{a_m}$ and a_n has a backward link $(a_n, b_n) \in G_{a_n}$

Conflicts k_a and k_b can also have an opposite link if either of the following conditions hold:

(3) Chunk a_m has a forward link $(a_m, b_m) \in F_{a_m}$ and a_n has a backward link $(a_n, b_n) \in G_{a_n}$.
(4) Chunk a_m has a backward link $(a_m, b_m) \in G_{a_m}$ and a_n has a forward link $(a_n, b_n) \in F_{a_n}$

Remark. Condition (1) and (2), and (3) and (4), respectively, are symmetric. This is because if chunk a has a forward link $(a, b) \in F_a$, then chunk b always has a backward link $(b, a) \in G_b$.

Using these conditions, we can use BFS or DFS to find the entire chain of conflicts from a specific conflict, either by selecting a subset of conditions for a specific direction (parallel or opposite), or any condition to find linked precedence decisions.

4.3.5 Scheduling effects of conflict chains

Because trains cannot change order within the conflict chain, we can observe direct effects on the possible scheduling of trains to each resource. First, we cover the parallel case. For two trains that have a parallel resource chain $\Gamma = \{k_a, k_b, k_c\}$ and on resources a, b, and c, and operations on a have a minimal duration of 2 units, on b they have 1 unit and on c they have 3 units, with the earliest possible scheduling the schedule diagram (similar to Gantt diagram) is shown in Figure 4.15.

Figure 4.15
Schedule diagram - parallel chain

Note: Trains are distinguished by color.

If the trains had the earliest possible start for resource a at 0, then the second train would be delayed by only 3 units. If we were to require that the first train is overtaken by the second train after a and before c, we would need to break the conflict chain by removing the conflict k_b, therefore rerouting either train to not use its chunk for resource b. This overtaking situa-

tion is only good if the first train has a big gap before it is considered delayed (the threshold of the objective is high). Such schedule is shown in Figure 4.16.

Figure 4.16
Schedule diagram - overtaking

Note: Trains are distinguished by color. Gray is overlap of intervals for resource b and d.

Now, we cover the opposite case. Because of the no swapping rule, the opposite conflict chains have a much bigger impact on the scheduling. Figure 4.17 shows the schedule diagrams for the two possible precedence cases.

Figure 4.17
Schedule diagram - opposite chain

Note: Trains are distinguished by color.

As we can see, the schedule of the second train to pass this chain has to be delayed until the first one passes through it entirely. This holds for arbitrarily long opposite chains, where the second train needs to wait until the first opposite train leaves its last chunk before the second train can enter its first chunk.

Furthermore, when looking at train routing from a safety perspective, an opposite conflict chain means that trains going in opposite directions are sharing a continuous sequence of resources (usually corresponding to sections of the railway track). In a situation where the train

breaks the schedule and enters the conflict chain before the other train leaves, we would have a head-on collision.

Remark. Conflict chains only impact the scheduling only if the affected trains want to pass it at the same time. If they pass the chain at different times then the precedence decision becomes trivial.

Due to these reasons, we attempt to break up these opposite conflict chains as much as possible when making routing decisions. If we want to allow the swap of priority on resources a and c, we need to break the conflict chain by rerouting either train to not use its chunk for resource b. By doing this we allow the schedule shown in Figure 4.18 where the priority is swapped. As you can see, the delay of the second train is entirely removed.

Figure 4.18
Schedule diagram - swapping

Note: Trains are distinguished by color.

Remark. While the trains in Figure 4.18 have no overlapping intervals, we still need the resource d. If both trains are scheduled to b then we do not have a timing collision, however we still break the no-swapping requirement.

Implementation details

To use the link graph in practice we list all possible links activations (operations or transitions) beforehand and maintain their current activation by checking a bitmap for active operations. This is because a single link can be activated by multiple different transitions and/or direct operations, for example the bottom case in Figure 4.11, forward link (a, b) has two activation counts, one direct and one transitional.

When we make changes to routes, thus changes to operations and transitions, we only update the links affected by these changes, as when making routing decisions we do them incrementally so only a small subset of possible operations and transitions is affected. This allows us to maintain the link graph continuously, without the overhead of recomputing it entirely for every single augmentation of the routing selection.

4.4 Route planning

To choose which routes are selected, we implement a routing procedure that gradually selects routes that break the opposite conflict chains for conflicts that have overlapping chunk time intervals, or are close to each other. This routing selection is motivated by the finding in the last section. For each opposite conflict chain, the second train can only enter the chunks in the chain only after the first train has passed them already, causing a significant delay.

4.4.1 Loss calculation

To quantify how good or bad the current routing selection is, we calculate the loss Λ_n of each train n as the sum of opposite chain lengths $|\Gamma_k(\Omega)|$ for each corresponding train conflict $k \in K_{n,\text{close}}$, that is deemed close,[5] based on the current route selection $\Omega = \{R_1, \ \ldots R_{|\Omega|}\}$,

$$\Lambda_n(\Omega) = \sum_{k \in K_{n,\text{close}}} |\Gamma_k(\Omega)|. \tag{4.13}$$

To calculate the loss (price) of the route λ_R, we have an augmented selection $\Omega_{\text{aug}} = \Omega \cup S$ where we add all routes $R \in S$ in section S are included, and then calculate the difference in train loss by removing the route R.

$$\lambda_R = \Lambda_n(\Omega_{\text{aug}}) - \Lambda_n(\Omega_{\text{aug}} \setminus \{R\}) \tag{4.14}$$

Each route loss calculation is done only for one section S at a time, by changing the selection of routes Ω, we change the conflict chains Γ and thus the train and the route losses.

The main motivation behind this is to gauge how much does removing the route break up the opposite conflict chains for the selected conflicts.

4.4.2 Procedure

The routing procedure is done in the following steps:

1. Get the average level time via randomized routing. This means that for each train we simulate passing the operation graph by selecting each successor at random with equal probability. We can get the level time by the earliest possible time for the operation by applying constraints for the lower bound for its start and minimal duration from its predecessor.
2. Get the set of close conflicts by checking which chunks have overlapping intervals. This is done while all operations are activated. We also stretch the interval on both sides

[5] How we select close conflicts is in the procedure subsection

to get conflicts that are not yet overlapping, but might overlap when the scheduling shifts them. We assign these conflicts to trains for loss calculation.
3. Initialize current routing selection at random, similar to step 1.
4. Freeze all current routing variables z_R by fixing their bounds. This reduces the ILP model size in preprocessing of the ILP model as the fixed variables are substituted.
5. Select all sections that have more than one route.
6. Optimize the selected sections in random order.

The optimization of each section is done in the following steps:

1. Calculate loss λ_R for each route $R \in S$ in the section S.
2. Unfreeze variables z_R for each route in the section.
3. Minimize the total price $\sum_{R \in S} \lambda_R \, z_R$ for the section by ILP optimization.
4. Freeze all variables z_R for each route in the section.

The ILP model for optimizing a section S has the variables z_R for each route R and the flow constraints in Equation 4.9, it can be written as

$$\min_{z_R} \sum_{R \in S} \lambda_R \, z_R, \tag{4.15}$$

$$\text{s.t.:} \sum_{R \in \rho_{\text{in}}(j)} z_R - \sum_{R \in \rho_{\text{out}}(j)} z_R = \begin{cases} -1 & \text{if } j \text{ is a start (source) junction} \\ 1 & \text{if } j \text{ is an end (sink) junction} \\ 0 & \text{otherwise} \end{cases}, \tag{4.16}$$

$$j \in J_S, \; z_R \in \{0, 1\}, \tag{4.17}$$

where J_S is the set of routing junctions in the section S, $\rho_{\text{in}}(j)$ is a set of incoming routes and $\rho_{\text{out}}(j)$ is a set of outgoing routes for junction j.

We iterate over sections because they are the smallest possible sets of dependent routes and the routing decision of each section can affect the losses of all other sections, and thus optimizing all sections at the same time would be problematic, because their interconnected nature makes it computationally infeasible. While a better than random order of sections could be utilized, we have not come up with a solution that would improve the loss optimization, compared to random order of sections.

We could also repeat the optimization steps or restart the optimization entirely and try for a better solution, but in practice there are no significant improvements in doing so. This is because most of the instances have some symmetry in their routing options where we might swap operations between trains without impacting the lengths of the chains.

4.5 Conflict resolution

Because two of the three winning solutions in DISPLIB have used a big-M formulation (Wolsey, 1998) for the constraints implied by the routing and precedence decisions, we have decided to try a different approach based on a *path-and-cycle* formulation (Lamorgese & Mannino, 2019)(Lamorgese et al., 2015), which is similar to the LBBD in Dubach et al. (2025b).

This approach does not use the big-M constraints that are often problematic (Pineda & Morales, 2019)(Codato & Fischetti, 2006). Choosing the value of the M greatly influences the performance of the optimizer; values that are too small cut off feasible solutions, leading to an incorrect model, and values that are too big weaken the LP relaxation, which then requires more nodes in the branch-and-bound search to arrive at an integer solution, and can even cause numerical instability.

Instead, we use an event graph which includes the selected alternative edges from precedence decisions, and we add feasibility cuts to prevent cycles and to enforce a conditional lower bound on delays based on the current precedence variables via the critical path. This eliminates the need for big-M constraints, as the highest coefficients are the lower-bounds for the delays. The main drawback for this approach is that we may need to add an exponentially growing number of cuts to remove the infeasible solutions. This is why we use the link graph to group these precedence decisions into chains to reduce the required number of variables and cycle cuts.

4.5.1 Event graph

To generate the times of each level and the chunk time intervals, we employ an event graph, where each level corresponds to one vertex of the graph (plus the origin). We add one edge for each active operation from its starting level to its ending level with the weight equal to the minimum duration of the operation. We also add one edge for each conflict based on the current value of the precedence variable from the end of the first chunk to the start of the second chunk with the weight equal to its release time. Figures 4.19 and 4.20 show such an event graph with both operation and precedence edges.

4.5.2 Cycle cuts

The MILP problem can assign values of precedence variables in such a way that the selection of alternative edges is inconsistent (there exists a cycle in the graph). This situation is shown in Figure 4.19, where alternative edges (j, u), (w, x) and (y, i) are part of a cycle.

Figure 4.19
Event graph - cycle

Note: Selected alternative edges are red. Alternative edges have their corresponding precedence variable.

Because we cannot remove the operation edges (we are working with fixed routes), we prevent the cycle by adding a no-good cut on the precedence variables in the cycle Π_C,

$$\sum_{p \in \Pi_C} p \leq |\Pi_C| - 1, \tag{4.18}$$

forcing any of the variables to change their value, preventing the cycle from forming. For our example, $\Pi_C = \{p_1, p_2, \bar{p}_3\}$, $\bar{p}_3 = 1 - p_3$.

4.5.3 Path cuts

For each active operation with an objective $o \in O_{a,\Delta}$, we have delay variable Δ_o. The MILP model tries to minimize these, but the event graph sets the earliest time t_o based on its critical path. This creates a conditional lower-bound for the delay variable Δ_o based on the current precedence values. Figure 4.20 shows such critical path for s, generating time $\mathrm{T}(s)$.

Figure 4.20
Event graph - critical path

Note: Critical path for s is red. Alternative edges on the critical path have their corresponding precedence variable.

We can enforce the conditional lower-bound of delay Δ_o, if it is violated, by adding a critical path cut,

$$\Big(\sum_{p\in\Pi_P} p - |\Pi_P| + 1\Big)\Big(\mathrm{T}(s) - \bar{t}_o\Big) \leq \Delta_o, \tag{4.19}$$

where Π_P is the set of precedence variables on the critical path, $\mathrm{T}(s)$ is the time of the starting level for o (in the current graph), and $\bar{t}_o$ is the objective threshold. This cut is active only when all the precedence variable Π_P along it are active. For our example in Figure 4.20, only p_1 and p_2 are in the set $\Pi_P = \{p_1, p_2\}$; the third precedence variable is not on the critical path.

If the objective is stepwise, Δ_o is binary, indicating that $t_o > \bar{t}_o$, then we just add an implication cut,

$$\sum_{p\in\Pi_P} p - |\Pi_P| + 1 \leq \Delta_o. \tag{4.20}$$

4.5.4 Conflict discovery

We iteratively discover the conflicts by finding the first overlapping pair of chunks on the same resources. We then use the link graph to find the entire chain Γ for the discovered conflict and use one binary precedence variable $p_\Gamma \in \{0, 1\}$ for all the conflicts in the chain, $p_\Gamma = p_k, \forall k \in \Gamma$.

Using the chain reduces the number of necessary variables and cycle constraints, because for a chain of two conflicts a and b, we would need two variables p_a and p_b and two cycle cuts $p_a - p_b \leq 0$ and $p_b - p_a \leq 0$. So for each connection in the chain, we reduce the number of necessary variables by one, and the number of necessary cycle constraints by two.

An additional advantage is that using the conflict chain prevents resource swaps, as only possible swap between two pairs of chunks must have their corresponding conflicts on the same conflict chain.

4.5.5 MILP model

The complete MILP model that is optimized in each step is the following:

$$\min_{\Delta_o, p_\Gamma} \sum_{o\in O_{a,\Delta}} c_o \Delta_o, \tag{4.21}$$

$$\text{s.t.: all cycle cuts ,} \tag{4.22}$$

$$\text{all path cuts,} \tag{4.23}$$

where c_o is the coefficient (if continuous) or increment (if binary) of the objective for the operation o. Cycle cuts have the form of Equation 4.18; path cuts have the form of Equations 4.19 and 4.20.

4.5.6 Procedure

The conflict resolution procedure is done in the following steps:

1. Optimize the current MILP model.
2. Update the event graph with current precedence values.
3. If the event graph contains a cycle, add the cycle cut (Eq. 4.18) for the smallest set Π_C. Go to step 1.
4. If any delay variable violates the conditional lower-bound, add a path cut (Eq. 4.19 or 4.20) for the most violated delay. Go to step 1.
5. Check if there are any conflicts in the chunk intervals. If yes, add the whole chain for the earliest conflict. Go to step 1.
6. Stop, we have a conflict free selection of precedences.

To better illustrate how the procedure works, Figure 4.21 shows a diagram of what each component of the conflict resolution procedure provides for the others, including the route planner.

Figure 4.21
Conflict resolution diagram

While we could add multiple conflicts and/or multiple cuts per iteration, we are trying to limit the number conflicts and cuts to only the necessary number, so the MILP model does not get bloated and thus slows down. This is why we only add one cut or conflict per iteration and utilize the previous solution as a warm start, speeding up the computation.

Tuning the MILP optimizer

As there is a significant number of cuts, we use a lazy constraint principle, where during the branch-and-bound procedure, each cut is treated as lazy and only added to the simplex table if it is violated. This is because by selecting a value for the precedence variable effectively

disables all the cuts where the precedence variable has the opposite value, and thus they do not need to be considered later in the search. This significantly reduces the computational demand of the model and allows us to optimize models with thousands of cuts.

We also increase the value of the mixed-integer programming gap (MIPGap)(Gurobi Optimization, 2024), to shorten the search to solutions that might not be optimal, but are good enough. If we have spare time, we decrease the gap after each run of the conflict resolution procedure in hopes of finding a better solution.

5. Results

Software and hardware

All procedures are implemented in the *C++* language (ISO, 2024), using *Gurobi* (Gurobi Optimization, 2024) as the MILP solver for both routing and conflict resolution. The source code is available from `https://github.com/svrc-jan/train-opt`. All computations are done on a computer with i7-9700F CPU and 16 GB of RAM.

Instance grouping

Because the DISPLIB library has 112 instances, we split them into 10 groups with approximately the same size (9 to 16 instances per group) based on their initial source (encoded in the name), which also corresponds to the structure of the problem. Unless specified otherwise, the presented results are the median across the instances inside the group. We feel that this number should be a good representation of the results as it is not skewed by a single instance within the group and thus provide us with a valid overview that can still be compared across the groups.

5.1 Aggregation

To gauge how well the aggregation of the instance data worked, Table 5.1 presents the initial instance data counts. We can see that the instances vary in size, with respect to the number of trains, operations, resources, etc. The most significant difference is between the number of operations compared to the number of operation-to-resource relations (ORR, sum of the number of required resources for each operation). While the *nor* instances assign at most one resource to a single operation, the other instances allow multiple resources per operation.

Table 5.2 shows the aggregation counts, and the relative reductions compared to the initial data. We provide the relative improvements to see how well the aggregation procedure reduced the count of the required objects. For example, the operation-to-level ratio gives how many fewer vertices we need in the event graph compared to using each operation as a vertex, i.e. how much we can parallelize the events. Similarly, the operation-to-route ratio gives how many fewer routing decisions we need to make compared to naively having a decision (most likely a binary variable) for each operation. The most impactful is probably the ORR-to-chunk ratio, as grouping the related resource conflicts is going to have a direct impact on how many conflicts we need to resolve to get a conflict free solution.

[1] Operation-to-resource relations, it is compared to chunks in Table 5.2.

Table 5.1

Op. / Route	1.17	1.13	1.24	1.06	1.05	2.49	2.55	20.38	1.15	1.15
ORR / Chunk	1.00	1.00	1.00	1.00	1.00	3.36	3.25	3.52	1.11	1.09

Table 5.3 shows additional percentages for each relevant instance group. First is the invalid transition junctions. It shows what percentage of junctions has an invalid transition; this is useful to see how many additional constraints we need to make to prevent the invalid transitions. Second is the optional level; this is the maximum percentage of levels that can be bypassed by an operation, it might be useful to choose another way of encoding the parallel events if there are too many optional levels. Third and fourth are the direct and parallel merges; telling us how effective each strategy is at merging ORR into chunks. The *nor* instance groups are omitted from Table 5.3, as they have all of these values at zero.

Table 5.3

5.2 Routing and conflict resolution

We set the timeout for the conflict resolution at 10 minutes, as is the initial value set by DISPLIB. Table 5.4 gives multiple improvement percentages, comparing random and optimized routing assignments. First is how much does the routing procedure reduce the total routing loss, second is how the final objective improved, and last is how much faster (or slower if negative) we arrived at a conflict free solution. It also includes the gap to the best-known solution. The last value is the absolute time to the first conflict free solution to show the speed of the conflict resolution procedure. If the conflict resolution procedure for the random routing assignment timed out without a solution for the instance, we set the improvement at 100%.

Table 5.4
Routing and conflict resolution

	nor1_crit	nor1_full	nor2_3	nor4	smi_close	smi_head	swi
loss improvement	49.1%	51.5%	48.5%	16.1%	66.3%	61.8%	1.1%
objective impr.	19.5%	100.0%	57.6%	100.0%	7.1%	3.3%	0.4%
time to sol. impr.	-11.7%	100.0%	90.8%	100.0%	-41.2%	-65.3%	-0.7%
best-known gap	2.1%	29.7%	23.8%	23.2%	61.2%	52.9%	100.0%
time to solution [ms]	46	596	4314	16021	24	40	1311

It is important to note that our conflict resolution procedure failed to solve 1 instance from the *nor4* group, 3 instances from the *swi* group and failed on all instances in the *nor5* and *wab* groups, within the 10 minutes. In total, we managed to solve 60% of the instances. In the solved instances, 60% of these are solved in 1 second from the start, and 42% are solved within 100 milliseconds.

Remark. All the best-known solutions from *swi* group have zero delay, this is why the best-known gap in Table 5.4 for *swi* is 100%, even though our solutions have small delays, relative to the overall train durations.

5.3 Time requirements

Table 5.5 shows how much time each step of the initial stage before conflict resolution takes place. This includes loading of the instance, aggregation of the instance data, creation of the link graph and then the routing optimization.

Table 5.5
Time requirements for initial stage

	nor1_crit	nor1_full	nor2_3	nor4	nor5	smi_close	smi_head	swi	wab_large	wab_small
Instance	1	18	7	43	78	5	9	57	19	13
Aggregation	0	2	0	8	15	1	1	5	1	1
Link graph	0	82	3	202	607	1	1	154	29	10
Routing	64	1560	172	5529	15351	33	37	184	1527	713

Note: All values are in milliseconds.

6. Discussion

6.1 Aggregation

From Tables 5.2 and 5.3, we can see that the aggregation of the initial data is successful. For all instance groups, except for the *swi* group, the operation-to-level ratio ranges from 1.46 to 2.84; this provides a significant reduction in the number of necessary vertices when creating the event graph, or other similar structure where we can leverage the parallel events. In turn, the *swi* group has an operation-to-route ratio of 20.4. This means that the operations in these instances cannot be aggregated into parallel events, but instead have long stretching routes of many operations that are aggregated into a single routing decision.

The most significant is the ORR-to-chunk ratio. While the *nor* and *wab* instances had missing or negligible reductions, due to the fact that they assign each operation a separate resource, the 3.25 to 3.52 reduction ratios for *smi* and *swi* instance groups provide a significant reduction in the number of conflicts that need to be resolved when scheduling. Because most combinatorial problems are considered NP-hard (Garey & Johnson, 1979), reducing the number of required decisions by a factor of over three should result in much faster solutions for these problems.

From Table 5.5 we can see that the time to do these aggregation steps is negligible, even compared to the process of loading the instance data itself, therefore it is always recommended to do them before doing any further solving or analysis.

The only questionable decision is regarding the use of parallel merges. While they may further reduce the number of necessary chunks, they also need more bookkeeping to track which parallel route we are taking. For a solution that dynamically updates the routing decision, it might be simpler to not merge the parallel chunks in favor of only increasing the number of chunks by a small percentage.

6.2 Link graph

The derivation of conditions for the linked conflicts in Section 4.3.4 from the alternative graph formulation in Section 4.3.3 via the use of the link graph is the main theoretical innovation presented in this thesis. We believe that it could be used to analyze and solve not only the train dispatching problem, but also any problem that uses resources in a blocking manner, like the blocking job-shop problem (BJSP).

We successfully use the link graph for both routing and conflict resolution, showing its potential for problems with blocking resource dependencies. It is important to note that prebuilding the entire possible graph ahead of time to allow for continuous updates using operation bitmaps is relatively fast, as you can see from Table 5.5, at most 8 times the amount of time to load the instance, usually faster.

From the routing time you can see that querying the link graph for conflict chains and updating it is also relatively fast, certainly faster than augmenting and searching the entire alternative graph for inconsistent selections would be.

6.3 Routing

The top-down routing decisions based on opposite conflict chains have proven to be quite reasonable; the improvement in solution quality can be clearly seen from Table 5.4. While it did increase the time to the first conflict-free solution for some of the groups, it also enabled us to solve the *nor1_full* and *nor4* instances, which all timed out for the random routing assignment. The routing decisions are clearly motivated by the structure of the problem and its safety effect of preventing trains going in the opposite direction from sharing resources.

There is, however, one main drawback compared to the bottom-up approaches of the winning DISPLIB solutions; we do not refine the routes during the optimization. This causes us to be stuck in suboptimal routes, meaning that we only improve a current feasible solution by tightening the MIPGap parameter of the MILP solver. It is, however, unclear how to combine our top-down routing approach with refinement, as the bottom-up solutions just use the best current available route without any consideration of the overall structure of the problem, treating it as a black-box.

6.4 Conflict resolution

The path-and-cycle formulation has proven to be quite effective for the small and mid-sized instances, getting a conflict-free solution within seconds or even fractions of a second. This seems to be the main advantage over the big-M formulation, where it takes them tens or hundreds of seconds to arrive at a solution (Dubach et al., 2025b), showing a significant speed-up, albeit at the cost of suboptimal solutions for some instances.

This is caused by the fact that they need to create a time variable for each level at least, plus two time variables for each chunk, and the corresponding temporal feasibility constraints. On top of that, they also need to use many simplex iterations to get feasible starting values for these variables. Our formulation uses the event graph to generate the level times and chunk intervals. Therefore, our initial MILP model is much smaller, only having the objective delay variables.

The failure to solve the *nor5* and *wab* instance groups corresponds to the fact that for these instances the resource chunk aggregation is not applicable, thus increasing the number of required conflicts to be resolved. It should be noted that the heuristic in Dubach et al. (2025b) also struggled with the same groups of instances, *nor5* and *wab*, but not with the three larger instances in the *swi* group as ours did.

While the gap to the best known solutions might seem high, it is important to note that these are solutions with unlimited time and computation resources and thus some gap is expected. The only other point of comparison is that only 8 teams in the competition provided at least one solution in more than half of the instance groups. Out of ten total groups, we fully solved five and solved the majority of instances in two more.

The main problem for the path-and-cycle formulation is the bloat of the MILP master problem, where we need thousands of cuts to arrive at a conflict-free solution, which in turn slows down the solution significantly, even when using the lazy constraint principle. The biggest possible improvement for the speed of this optimization problem would be some sensible cut cleanup procedure that would remove the redundant cuts that are no longer necessary. We have made an effort to implement such a cleanup based on the removal of non-binding or dominated cuts, but it hindered the performance of the solver as these updates were more time-consuming than just simply letting Gurobi's lazy constraint handling deal with them.

7. Conclusion

7.1 Goals and innovations

We have developed procedures for both routing and conflict resolution, and described them in detail. We have solved the majority of the instances in the DISPLIB benchmark library using these procedures. The routing decisions are done using a top-down approach, where we prevent trains going in opposite directions from using the same resources, which not only reduces the delay, but also improves the safety aspect of the affected schedules.

The conflict resolution is done using the *path-and-cycle* formulation, which is not used by any of the winning solutions for DISPLIB, furthering the research of the train dispatching problem (TDP). Its main motivation is the removal of big-M constraints that weaken the MILP relaxation and cause numerical instability. While we have not surpassed the state-of-the-art for the TDP, our procedure provides a significant reduction in time to achieve a conflict-free solution, albeit at the cost of suboptimal objective values for some instances. This should be sufficient for true real-time dispatching of trains.

Both routing and conflict resolution rely on an efficient aggregation of the initial data to reduce the problem size and the use of an innovative *link graph* structure. The aggregation section, while inspired by previous solutions, clearly describes each structure and how to create it, and can be used for any other solution or a problem related to TDP.

We introduce the link graph to keep track of resource dependencies and to allow us to get structural implication rules for our resource precedence decisions. The formulated conditions for these rules are much easier to use in practice than conditions described in the relevant literature. The link graph can be updated incrementally to allow for efficient augmentation based on the specific routing selection.

7.2 Future work

There are two main possible improvements to our current solution. The first one is the implementation of a rerouting procedure where the initially selected routes would be adjusted based on the current suboptimal solution. The second one is the cut cleanup procedure for the master MILP problem in the conflict resolution, where our problem becomes bloated with cuts that might no longer be necessary, slowing down the optimization.

Another related area of research is the use of the introduced link graph for related problems, such as the blocking job-shop problem, where it could be used to reduce the number of required variables and constraints, similar to how we use it for conflict resolution.
